

On the Infrared, Optical and High Energy Emission from the Anomalous X-Ray Pulsar 4U 0142+615

Ü. Ertan¹ and K. S. Cheng²

Department of Physics, The University of Hong Kong, Hong Kong, China

ABSTRACT

We show that the observed *pulsed* optical emission of the anomalous X-ray pulsar 4U 0142+61 can be accounted for by both the magnetar outer gap models and the disk-star dynamo gap models, therefore is not an evidence in favor of one of these models as its responsible mechanism. Nevertheless, the estimated high energy gamma-ray spectra from these models have different power-law indices, and can be tested by future observations of the Gamma-ray Large-Area Space Telescope (GLAST). Furthermore, we show by analytical estimations that the expectations of a standard disk model is in agreement with the observed *unpulsed* optical and infrared luminosities of the AXP 4U 0142+61.

Subject headings: pulsars: individual (SGR 1900+14) — stars: neutron — X-rays: bursts — accretion, accretion disks

1. Introduction

Anomalous X-ray pulsars (AXPs) are neutron stars (NSs) which are characterized by their persistent X-ray luminosities ($L_x \sim 10^{34} - 10^{36}$ ergs s⁻¹) which are well above their rotation powers. Observations show no evidence for the existence of massive companions. Their periods are clustered in a remarkably narrow range $P \sim 6 - 12$ s. Some of the AXPs belong to SNRs which show that they are young objects (See Mereghetti et al. 2002, for a review of AXPs). The X-ray luminosities, periods, and black body temperatures of AXPs are similar to those of soft gamma-ray repeaters (SGRs) (see Hurley 2000 for a review). Furthermore, recently reported SGR-like bursts from two of the AXPs (Kaspi & Gavril 2002, Gavril et al. 2002) imply that these sources probably have similar origins.

Magnetar models (Dunacan & Thompson 1992, Thompson & Duncan 1995) are successful in explaining the fluences and the luminosities of the normal ($L \lesssim 10^{42}$ erg s $^{-1}$) and the giant ($L \gtrsim 10^{44}$ erg s $^{-1}$) super-Eddington bursts of SGRs. In the magnetar models, surface magnetic fields are $\gtrsim 10^{14}$ G, and huge magnetic energy release through instabilities from inside the NS is the source of these bursts. The persistent thermal X-ray emission was suggested to be due to the surface heating by magnetic field decay, while the accelerated particles in the magnetosphere by the Alfvén waves produced by the small scale fractures on the NS surface could be the source of the non-thermal emission (Thompson & Duncan 1996). Spin-down torque is provided by the magnetic *dipole* radiation. Despite the success of the magnetar model in explaining the burst energetics, it can account for the period clustering of SGRs and AXPs only in one set of decay models with special conditions (Colpi, Geppert & Page 2001).

On the other hand, fall-back disk models, which have difficulties in explaining the short time scales of the super-Eddington bursts, can account for the period clustering and the persistent X-ray emission of these sources (Chatterjee, Hernquist & Narayan 2000; Alpar 2001; Marsden, Lingelfelter & Rothschild 2001). The enhancement phase of the persistent X-ray emission following the giant flare of the SGR 1900+14 can be explained by the post-burst release of the inner disk which has been pushed back by the burst energy (Ertan & Alpar 2003) (see also Lyubarsky, Eichler & Thompson (2002) for an explanation based on crust cooling after being heated by the burst energy). Moreover, it was shown that the young NSs with fall-back disks can produce AXPs within the time scales of the ages of their associated supernova remnants with reasonable parameters (Chatterjee & Hernquist 2000; Ekşi & Alpar 2003a,b).

Magnetar models have no detailed predictions for the IR and optical emissions seen from the AXPs which, in this work, is one of our main concerns based on the disk models. Out of five observed AXPs (and two candidates), four sources were reported to have IR counterparts (Kaspi et al. 2002, Israel et al. 2002, Israel et al. 2003). One of them (4U 0142+61) was also detected in the R-band (Hulleman et al. 2000). The optical/IR luminosities of these AXPs lie above the extrapolation of the black body components of their X-ray spectra (Hulleman et al. 2001, Wang & Chakrabarty 2002, Israel et al. 2003) indicating different origins for the optical/IR emission, and the thermal X-rays likely to be emitted near the NS surface. The observed ratio of the total R-band luminosity to the X-ray luminosity is $\sim 1.4 \times 10^{-4}$ for AXP 4U 0142+61 (Hulleman et al. 2000, Hulleman 2001), and was claimed to be too low for the origin of the optical light to be an accretion disk. Kern and Martin (2002) reported that the optical (in the R-band) emission from the AXP 4U 0142+61 has a pulsed component with a pulsed fraction $h_R \simeq 0.27$ which is much higher than the X-ray pulsed fraction $\sim 5\%$ (1 – 2 keV), which strongly suggests different emission sites for the pulsed

X-ray and optical emissions. It was argued that the pulsed optical radiation is an indication that AXPs are magnetars.

In present work, we show that the pulsed optical emission can be accounted for by both the disk-star dynamo gap model (Cheng & Ruderman 1991) and the magnetar outer gap model (Cheng & Zhang 2001), and does not exclude one or the other (Sections 2 & 3). In Sec. 4, we show that the two models can be observationally tested through their expected different high energy gamma-ray spectral characteristics. Furthermore, in Sec. 5, we show by analytical estimations that the R and K-band luminosities expected from a standard disk model is in agreement with the observations of the AXP 4U 0142+61.

2. Disk-Star Dynamo Model

For simplicity, we consider a NS dipole magnetic field aligned with the spin axis. When the inner rim of a Keplerian disk rotates faster than the neutron star, a gap (accelerator) is formed around the null surface ($\mathbf{\Omega} \cdot \mathbf{B} = 0$) separating the charges in the magnetosphere. The electromotive force of the disk-star dynamo (see Cheng and Ruderman (1991) for details, CR thereafter) is given by

$$\mathcal{E}(r) = \int_{r_0}^r (\Omega_K(r) - \Omega_*) B_z(r) \frac{r dr}{c} \quad (1)$$

where $B_z(r)$ is the vertical component of the magnetic field through the disk, $\Omega_K(r)$ the local Keplerian angular velocity of the disk, Ω_* the angular frequency of the NS, and r_0 the inner radius of the disk. In a stationary gap, the electromotive force is balanced by the potential drop V_g across the gap. Substituting $\Omega_K(r) = (GM/r^3)^{1/2}$ in Eq.1, and neglecting the effects of inflowing disk matter, we obtain

$$\mathcal{E}(r) = R_*^3 B_* \left[\frac{2}{5} \left(\frac{GM_*}{c^2} \right)^{1/2} \left(\frac{1}{r_0^{5/2}} - \frac{1}{r^{5/2}} \right) - \frac{\Omega_*}{c} \left(\frac{1}{r_0} - \frac{1}{r} \right) \right] \quad (2)$$

where R_* , B_* , and M_* are the radius, surface magnetic field and the mass of the NS respectively. Whether the gap is closed or open depends on how close the co-rotation radius $r_c = (GM/\Omega_*^2)^{1/3}$ is to the inner disk radius r_0 . If r_0 is less than $1.8 r_c$ the gap cannot close (the geometry of the open and closed gaps are given in Figs. 2 & 3 of CR). In the limit $\Omega_* \ll \Omega_K(r_0)$ the potential drop in Eq.(2) can be as high as

$$\mathcal{E}(r) \sim 4 \times 10^{14} r_{0,8}^{5/2} B_{*,12} \left(\frac{M}{M_\odot} \right)^{1/2} R_{*,6}^3 \left[1 - \left(\frac{r_0}{r} \right)^{5/2} \right] \text{ V} \quad (3)$$

where we use the notation $A = A_i \times 10^i$. This potential drop can only be reached by a static gap in which the pair production is negligible. In a more realistic stationary gap, the potential drop V_g is limited by the flow of electrons and positrons through the gap, especially when there is copious amount of X-ray photons traversing the gap. The X-rays are up-scattered by the inverse Compton collisions with the gap accelerated electrons and positrons. The gamma-rays produced by these inverse Compton scatterings create secondary e^\pm pairs through the collisions with the X-rays. These secondary pairs emit synchrotron emission out of the gap, which we test whether to be responsible for the observed pulsed optical emission. For such a pair production limited gap, the maximum potential drop can be estimated as

$$V_g = 6 \times 10^{10} L_{X,36} \left(\frac{\langle E_x \rangle}{1 \text{ keV}} \right)^{-1} B_{*,12}^{-1/2} R_{*,6}^{-1} \text{ V} \quad (4)$$

(CR). The energies of the primary pairs accelerated in this potential drop V_g are limited by their collisions with the X-ray photons. On the other hand, the gap power is limited by the power of the inflowing disk matter from r_c down to the inner disk radius r_0 ,

$$P \sim GM\dot{M} \left(\frac{1}{r_0} - \frac{1}{r_c} \right). \quad (5)$$

The inner disk radius can be written as

$$r_0 \simeq \beta \frac{r_A}{2} = 2.9 \times 10^8 \beta L_{X,36}^{-2/7} B_{*,12}^{4/7} \left(\frac{M_*}{M_\odot} \right)^{1/7} R_{*,6}^{10/7} \text{ cm} \quad (6)$$

(Ghosh & Lamb 1979) where r_A is the Alfvén radius and $\beta \sim 1$. For the AXP 4U 0142+61, $r_c \sim 7 \times 10^8$ cm, and the X-ray luminosity is $L_x = 6.5 \times 10^{35}$ ergs s⁻¹ for a source distance $d = 3$ kpc. d was reported to be greater than 2.7 kpc (Hulleman et al. 2000). The accretion rate is related to the X-ray luminosity through $\dot{M} = L_x R_*/GM \sim 3.4 \times 10^{15}$ g s⁻¹. Then, Eqs. (5) & (6) give a gap power $P_g \sim 1 \times 10^{33}$ ergs s⁻¹. The fraction of the gap power that is taken out of the gap by the secondary pairs depends on the pair production optical depth of the X-rays to primary gamma-rays. The density of the thermal X-ray photons at $r \sim r_0$ can be estimated as

$$\langle n \rangle \sim \frac{L_x}{4\pi(r_0)^2 c \langle E_x \rangle} \sim 10^{16} \text{ cm}^{-3} \quad (7)$$

where $\langle E_x \rangle \approx 3kT$ is the typical energies of the X-rays. For 4U 0142+61, $3kT \approx 1.2$ keV (Israel et al. 1999, Paul et al. 2000, Mereghetti et al 2002, Juett et al. 2002). The optical depth for the pair production of the primary gamma-rays with the soft X-rays becomes

$$\tau \sim \langle n \rangle \sigma_p l \sim (10^{16} \text{ cm}^{-3}) (10^{-25} \text{ cm}^2) (5 \times 10^8 \text{ cm}) \sim 0.5 \quad (8)$$

where $\sigma_p \approx 10^{25} \text{ cm}^2$ is the cross section for the pair production, and $l \sim r$ is the length of the gap along the field lines (l can exceed r considerably due to the azimuthal winding

of the magnetic field lines across the gap). Eq.(8) implies that about half of the gap power is transferred to the secondary e^\pm pairs. We investigate whether the synchrotron emission from these secondary pairs just out of the gap can account for the observed optical pulsed emission from AXP 4U 0142+61.

Energy distribution of the secondary e^\pm pairs can be approximated as

$$N_e \sim \gamma^{-2} \ln \left(\frac{\gamma_{\max}}{\gamma} \right) \quad (9)$$

(Cheng, Ho & Ruderman 1986) where γ is the Lorentz factor of the secondary electrons and positrons such that $\gamma_{\min} < \gamma < \gamma_{\max}$. The synchrotron energy spectrum from these secondary pairs is given by

$$f(E_\gamma) \propto \int_{\gamma_{\min}}^{\gamma_{\max}} d\gamma N_e(\gamma) F(x) \quad (10)$$

where $F(x) = x \int_x^\infty K_{5/3}(y) dy$, $K_{5/3}$ is the modified Bessel function, $x = E_\gamma/E_{\text{syn}}$, and $E_{\text{syn}} \simeq (3/2) \gamma^2 \hbar (eB/m_e c)$. The observed energy spectrum becomes

$$\mathcal{F}(E_\gamma) \approx \frac{1}{\Delta\Omega d^2} f(E_\gamma) \quad (11)$$

where $\Delta\Omega$ is the beaming solid angle of the synchrotron emission, and d is the distance to the source. The total synchrotron luminosity L_{syn} is found by integrating $f(E_\gamma)$ overall frequencies. The lower cut-off of the spectrum is determined by the minimum Lorentz factor γ_{\min} of the secondary pairs for which we take $\gamma_{\min} = 1$. The maximum Lorentz factor of the secondary pairs is $\gamma_{\max} \sim \text{MeV}/\langle E_x \rangle \sim \text{few} \times 10^3$ (Cheng, Ho, & Ruderman 1986; Cheng & Ding 1994). The exact position of γ_{\max} does not affect the results significantly, we take $\gamma_{\max} = 3 \times 10^3$. The synchrotron radiation is emitted at a radial distance $r \gtrsim r_0$ where the magnetic field strength reduces to about $\sim 3 \times 10^4$ G for a dipole field with $B_* \sim 10^{12}$ G on the surface of the NS. The resultant photon spectrum of the synchrotron emission is given in Fig. 1.

Our aim is to compare the model pulsed optical luminosity in the R-band with that of the observations. The ratio of the observed optical luminosity in the R-band ($\sim 1.7 - 2.1$ eV) to the X-ray luminosity was reported to be $\approx 1.4 \times 10^{-4}$ from the unabsorbed fluxes (Hulleman et al. 2000) with a pulsed fraction of the optical light $h_R \sim 0.3$ (Kern & Martin 2002). Then, the observed *pulsed* R-band luminosity is $L_R^{\text{obs}} \sim 2.5 \times 10^{31} (\Delta\Omega/4\pi)$ ergs s^{-1} for $L_x \simeq 6 \times 10^{35}$ ergs s^{-1} where $\Delta\Omega$ is the beaming angle of the synchrotron emission. To compare our results with the observations, we calculated the ratio of the synchrotron R-band luminosity to the total synchrotron luminosity and find that $L_R/L_{\text{syn}} \approx 1 \times 10^{-2}$.

Since the pair production optical depth provided by the soft X-rays to the primary gamma-rays is around one half, $L_{\text{syn}} \sim P_{\text{gap}}/2 \sim 5 \times 10^{32} \text{ ergs s}^{-1}$ for the AXP 4U 0142+61, which means $L_{\text{R}} \approx 5 \times 10^{30} \text{ ergs s}^{-1}$. For a beaming angle $\Delta\Omega \sim 2.5$, the optical pulsed luminosity estimated by the disk-star dynamo model is in agreement with the observations.

3. Magnetar Model

The possible gamma-ray emission properties from the outer gaps for both AXPs (with soft thermal X-ray input) and SGRs (including the effect of the hard X-ray component) has been worked in detail by assuming dipole magnetar fields with $B_* \gtrsim 10^{14} \text{ G}$ (Cheng & Zhang 2001, Zhang & Cheng 2002). In the outer gap models of AXPs, the primary gamma-rays are produced by the curvature emission of the accelerated primary electrons and positrons inside the gap (Cheng & Zhang 2001), which is different from the gamma-ray production mechanism of the disk-star dynamo model. The primary gamma-ray luminosity, that is, the power provided by the magnetar outer gap can be written as

$$L_{\gamma} \approx 4.0 \times 10^{32} \left(\frac{f}{0.5} \right)^3 \left(\frac{B_*}{10^{14} \text{G}} \right)^2 \left(\frac{P}{6\text{s}} \right)^{-4} \left(\frac{R_*}{15\text{km}} \right)^6 \text{ ergs s}^{-1} \quad (12)$$

(Zhang & Cheng 1997) where f is the fraction of the volume of the outer magnetosphere occupied by the outer gap which is given by

$$f \approx 0.68 \left(\frac{p}{6\text{s}} \right)^{7/6} \left(\frac{B}{10^{14} \text{G}} \right)^{-1/2} \left(\frac{T_s(\theta)}{5 \times 10^6 \text{K}} \right)^{-2/3} \left(\frac{R_*}{15\text{km}} \right)^{-3/2} \quad (13)$$

where $T_s(\theta)$ is the surface temperature of the magnetar. Its dependence on the polar angle θ with respect to the magnetic axis is weak and may be ignored. It should be noted that if $f > 1$ an outer gap cannot be formed (Zhang & Cheng 1997). For the AXP 4U 0142+61, the reported period is $p = 8.69 \text{ s}$ and the surface magnetic field estimated from $B = 3.3 \times 10^{19} (P\dot{P})^{1/2}$ is around $\sim 1.4 \times 10^{14} \text{ G}$ (Mereghetti et al. 2002), and the corresponding fractional size of the outer gap is $f \approx 0.89$. Then the outer gap power of 4U 0142+61 becomes $P_g \sim 1 \times 10^{33} \text{ erg s}^{-1}$, which is roughly the same as the gap power of the disk-star dynamo model. Similar to the disk-star dynamo model gap, secondary pairs, produced by the collisions between the primary gamma-rays and X-ray photons originating from the NS, emit synchrotron radiation out of the gap. Unlike the disk-star dynamo gap, the outer gap of an isolated NS extends to near the light cylinder radius $r_l = c/\Omega_*$ which is $\sim 4 \times 10^{10} \text{ cm}$ for 4U 0142+61. Replacing r_0 by $\sim r_l/3$, where the magnetic field decreases to about 10^2 G , and setting $l = r_l$ in Eqs.(7 & 8), we obtain the pair production optical depth $\tau_p \sim 0.03 L_{\text{x},36}$. For the maximum primary gamma-ray energies $\sim \text{few GeV}$ (Cheng & Zhang 2001), the maximum

Lorentz factor of the secondary pairs are $\sim \text{few} \times 10^3$. In the calculations, we set $\gamma_{\min} = 1$ and $\gamma_{\max} = 3 \times 10^3$. Following the same numerical calculations as that of the disk-star dynamo model, we found from the resultant spectrum (Eq.10) that the ratio L_R/L_{syn} is about 3×10^{-2} . The total synchrotron luminosity of the secondary pairs $L_{\text{syn}} \sim \tau_p P_g \simeq 3 \times 10^{31} \text{ ergs s}^{-1}$, and the corresponding pulsed R-band luminosity is $L_R \sim 3 \times 10^{-2} L_{\text{syn}} \sim 9 \times 10^{29} \text{ ergs s}^{-1}$. With a solid angle $\Delta\Omega \sim 0.5$ of the beamed synchrotron emission, magnetar model can also account for the observed pulsed optical luminosity of the AXP 4U 0142+61 in the R-band. The expected synchrotron photon spectrum is presented in Fig. 1. The weakness of the magnetar model for AXP 4U 0142+61 is that if the surface magnetic field of this source is $\sim 1.4 \times 10^{14} \text{ G}$ (Mereghetti et al. 2002), then the fraction f of the outer magnetosphere occupied by the outer gap (Eq. 13) exceeds unity for R_* less than about 13.9 km. This would mean that there is no outer gap of 4U 0142+41 at all (Zhang & Cheng 1997). On the other hand, if the outer gap indeed exists in 4U 0142+61 this implies that the equation of state (EOS) of this source cannot be soft EOS (cf. Shapiro & Teukolsky 1983) with magnetar dipole fields.

The spectral cut-off of the disk-star-dynamo model lies at the X-rays, whereas it is at about 10 eV for the magnetar model. However, the expected X-ray luminosity from the disk-star dynamo model is much less than the observed pulsed X-ray emission which is very probably emitted near the NS, and is not likely to be tested by the observations. In the next Section, we show that the two models could be distinguished through their high energy gamma-ray spectral properties.

4. High Energy Emission from the Magnetar and the Disk-Star Dynamo Models

The estimated high energy (keV - $\sim 10 \text{ GeV}$) emission spectra of the magnetar and the disk-star dynamo gap models are different, although their total high energy luminosities are similar. The outer gaps of magnetar models, which lie close to the light cylinder, are optically thin to the inverse Compton scattering of the X-rays by the gap accelerated pairs. These pairs emit beamed curvature radiation along the outer gap. The resultant spectra have been worked for both AXPs and SGRs (Cheng & Zhang 2001, Zhang & Cheng 2002). The energy distribution of the primary e^\pm pairs in the gap is given by

$$\frac{dN}{dE_e} \propto \left(\frac{\gamma}{\gamma_o} \right)^{-16/3} \quad (14)$$

(Zhang & Cheng 1997) where $\gamma_o \approx 2.8 \times 10^7 f^{1/2} B_{12}^{1/4} P^{-1/4} (R_*/10 \text{ km})^{3/4}$. The Lorentz factor γ is given by $\gamma(x) \approx \gamma_o x^{-3/4}$ for $x_{\min} \leq x \leq x_{\max}$ where $x = s/r_l$ and s is the local

radius of the curvature. For the AXP 4U 0142+61, $\gamma_o \sim 5 \times 10^7$. The value of x_{\min} depends on the magnetic inclination angle α , and it is $\sim 2/3$ for $\alpha = 45^\circ$ and $\sim 2/5$ for $\alpha = 60^\circ$. x_{\max} could be taken ~ 2 (Cheng & Zhang 2001). The primary pairs with Lorentz factors between γ_{\min} and γ_{\max} emit curvature radiation with typical energies $E_\gamma \approx (3/2)\hbar\gamma^3(c/s) \lesssim \text{GeV}$. Above the characteristic energies spectrum has an exponential cut-off, while $I(\nu) \propto \nu^{1/3}$ for $E < E_{\gamma_{\min}}$. The detailed model spectra of AXPs for different period, magnetic field and inclination angles are given in Cheng & Zhang (2001).

On the other hand, for the disk-star dynamo model, the energies of the gap accelerated e^\pm pairs are limited by the inverse Compton collisions by the X-rays. Thereby produced gamma-ray photons create e^\pm pairs via collisions with the X-rays. The energy distribution of the pairs in the gap can be approximated by Eq. (9). For a power-law energy distribution $N_e(\gamma) \propto \gamma^{-m}$ of the pairs, the resultant intensity spectrum of the up-scattered X-rays can be written as $I_c(\nu) \propto \nu^{-p}$ with $p = (m - 1)/2$. For the pair distribution given by Eq. (9), we have $m = 2 + [\ln(\gamma_{\max}/\gamma)]^{-1}$. The variation of the term in square brackets is small along the large range of the Lorentz factors. For a variation of γ_{\max}/γ from ~ 5 to $\sim 10^3$, p changes from 0.6 to 0.8.

We see that the expected high energy gamma-ray spectra of the magnetar and the disk-star dynamo models have very different spectral power-law indices. The model luminosities are high enough such that they can be tested by the future gamma-ray mission GLAST observations (Cheng & Zhang 2001).

5. Unpulsed Optical/IR Emission

Since the unpulsed component of the optical/IR emission is expected to be isotropic, there is no beaming correction, and therefore $(L_R/L_x)_{\text{observed}} \sim 10^{-4}$ for the unpulsed emission of the AXP 4U 0142+61. The reported IR and optical magnitudes are $K \approx 19.4$ mag and $R \approx 25$ mag (Hulleman et al. 2000, Hulleman 2001). The estimated interstellar extinction in the R-band is $A_R = 4.4$ mag, then it is expected that $A_K \simeq 0.5$ in the IR band. We estimate that the ratio of the observed K-band flux to that of R-band $(L_K/L_R)_{\text{observed}}$ is $\sim 10^{-1}$. Now, we will compare these observations with the expectations of a standard accretion disk model.

We take $\dot{M}_* = \eta \dot{M}_{\text{in}}$ where η is the fraction of the disk mass flow rate which is accreted on to the NS, and assume that the mass flow through the inner disk regions emitting in the K and R bands can be represented by a steady state mass flow. The local dissipation rate

$D(r)$ of the disk at the radial distance r in steady state is given by

$$D(r) \simeq \frac{3}{8\pi} \dot{M} \frac{GM}{r^3}. \quad (15)$$

For $L_x \sim 10^{36}$ ergs s $^{-1}$, the accretion rate onto the NS becomes $\dot{M}_* \sim 5 \times 10^{15}$ g s $^{-1} \sim \eta \dot{M}_{\text{in}}$. We obtain

$$D(r) \approx 1.2 \times 10^{14} r_9^{-3} \eta^{-1} \text{ergs s}^{-1} \text{cm}^{-2} \quad (16)$$

where r_9 is the radial distance in units of 10^9 cm. The corresponding local effective temperature of the disk becomes

$$T_{\text{eff}}(r) = \left(\frac{D(r)}{\sigma} \right)^{1/4} \simeq 3.8 \times 10^4 r_9^{-3/4} \eta^{-1/4} \quad (17)$$

where σ is the Stefan-Boltzmann constant. The central wavelength of the R-band is $\lambda_R \simeq 138$ nm. The effective temperature that gives the maximum of its black body emission in the R-band is $kT \sim 1$ eV. Equating $kT_{\text{eff}} = 1$ eV in Eq. (17) we find $r(kT \sim 1 \text{ eV}) \sim 4.8 \times 10^9 \eta^{-1/3}$ cm. Then,

$$\frac{L_R}{L_x} \simeq \left(\frac{R_*}{2r(kT = 1 \text{ eV})} \right) \simeq 1 \times 10^{-4} \eta^{-2/3} \quad (18)$$

which is in agreement with the observed ratio reported by Hulleman et al. (2000) for the values of η near unity. To estimate the IR flux from the disk, we equate $kT_{\text{eff}} \simeq 0.1$ eV in Eq. (17), and find $r(kT \simeq 0.1 \text{ eV}) \simeq 1 \times 10^2 r_9 \simeq 10^{11} \eta^{-1/3}$ cm. Eq. (17) gives $(L_K/L_x) \sim 10^{-5} \eta^{-2/3}$, that is, $L_K/L_R \sim 10^{-1}$ (independent of η) which is also consistent with the observations of the AXP 4U 0142+61. On the other hand, shorter wavelength optical and UV emission which is expected from the innermost regions of the disk, could be effectively absorbed due to increasing IS absorption with decreasing wavelength along these energies.

Our estimates remain consistent with the observations as long as η is greater than about $\sim 30\%$. Ekşi & Alpar (2003a) showed that fall-back disks can produce AXP period and period derivatives in time scales consistent with their SNR ages using dipole magnetic fields with $B_* \sim 10^{12} - 10^{13}$ G. They estimated that η could be as low as 0.01 for some AXPs, and pointed out that η could be higher if the mass loss from the disk due to propeller effect during the life time of the AXPs and SGRs is taken into account. From the disk model parameters of AXP 0142+61 (Ekşi & Alpar 2003b), we can estimate its present disk mass flow rate as $\sim 3 \times 10^{16}$ g s $^{-1}$, that is, $\eta \sim 15\%$ which is consistent with our rough estimate within a factor $\sim 2 - 3$. More detailed numerical calculations of the optical/IR emission from the AXPs and SGRs will be presented in a separate work.

In present disk models of AXPs, IR and optical luminosities are assumed to be dominated by the X-ray irradiation of the disk by the central X-rays (Perna, Hernquist & Narayan

2000; Perna & Hernquist 2000). For the observed IR emission from the AXP 1RXS J1708-40, these X-ray irradiated disk models give unreasonably large inner disk radii ($> 10^{11}$ cm) and restrict the radial extend of the disk $\Delta R \sim 5 \times 10^{11} - 10^{12}$ cm) (Israel et al. 2003). Optical/IR emission from the low-mass X-ray binary disks has long been known to be X-ray irradiation dominated, and this could be the motivation to include the X-ray irradiation in the AXP disk models. However, X-ray could be inefficient for the AXP disks due to the following reason. The observationally supported irradiation of the outer disk of low mass X-ray binaries (LMXBs) has to be indirect, very probably due to a central extended hot corona (see e.g. Dubus et al. 1999), because of the self screening of the disk. A central, extended hot corona can be fed by the thermally unstable matter from the inner disk where the thermal instabilities are most effective (Shaviv and Wehrse 1986). However, the innermost disk regions of AXPs (and SGRs) are cut by the dipole magnetic fields of their neutron stars, which are orders of magnitude higher than the magnetic fields of the NSs in LMXBs. Therefore, the X-ray irradiation that prevails at the LMXB disks, does not necessarily be effective for the AXP and SGR disks, though it is not impossible. Therefore, in our calculations we ignore the X-ray irradiation. Observed IR/optical luminosity of AXPs do not restrict the outer disk radius in our explanation. That is, the outer disk expands freely in the low viscosity state, and needs not to be passive (no viscosity) as proposed by Menou et al. (2001). On the other hand, we expect that the inner disk radius is around the Alfvén radius ($\sim 5 \times 10^8$ cm) which is about an order of magnitude less than the estimated radial distance at which most of the optical R-band luminosity is emitted ($\sim 5 \times 10^9$ cm). Inner rim of the disk can be irradiated by the X-rays, but the resultant emission is expected to be in the UV band which is easily absorbed by the ISM. It is hard to estimate the detailed emission spectrum from the innermost disk due to the uncertainties in the physics of the disk-magnetosphere interaction. Part of the inner disk matter outflowing due to the propeller effect may also modify the emission from the underlying innermost disk where higher energy optical photons emitted.

6. Conclusions and Discussion

We have shown that : (i) the observed optical *pulsed* emission from the AXP 4U 0142+61 can be explained by means of both the magnetar outer gap model and the disk-star dynamo gap model, and therefore does not eliminate either of the models, (ii) the two models, which do not provide an observational test through their different synchrotron X-ray luminosity due to the dominating X-ray luminosity from the NS, can be tested observationally via their estimated high energy gamma-ray spectra by the Gamma-ray Large-Area Space Telescope (GLAST), (iii) the IR and optical emission expected from a standard accretion disk model is

in agreement with the reported unpulsed IR and optical luminosity of the AXP 4U 0142+61 for the ratio of the accretion rate onto the NS to the disk mass flow rate $\eta \gtrsim 30\%$.

Our estimation for η is roughly consistent with that obtained from the fall-back disk model of AXP 0142+61 (Ekşi & Alpar 2003b). The IR to X-ray luminosity ratio of the AXP 1E 2259+58 is similar to that of 4U 0142+61 (Hulleman 2001), and can be explained by similar arguments. The reported L_R/L_x ratio of AXP 1RXS J1708-40 is $\sim 2 \times 10^{-3}$ (Israel et al. 2003) which is about 10 times higher than that of 4U 0142+61, and might indicate relatively more efficient mass outflow due to the propeller effect in this system with $\eta \sim 1/30$. Detailed numerical disk calculations to estimate the optical/IR luminosities of AXPs and SGRs and comparisons with their period and period evolution models will be presented in future work.

We thank Ali Alpar and Yavuz Ekşi for discussions, and comments on the manuscript.
